+kobject_uevent(&mod->mkobj.kobj, KOBJ_ADD);
We need to finish all async code before the module init sequence is done. This has potential to deadlock. For example, a newly walking this with preempt disabled. In all the failure paths, we call synchronize_sched(), but we don't want to slow down the success path, so use actual RCU here.

Note that module_alloc() on most architectures creates W+X page mappings which won't be cleaned up until do_free_init() runs. Any code such as mark_rodata_ro() which depends on those mappings to be cleaned up needs to sync with the queued work - ie

+/*
To keep the bandwidth of -deadline tasks under control
we need some place where:
- store the maximum -deadline bandwidth of each cpu;
- cache the fraction of bandwidth that is currently allocated in
each root domain;

This is all done in the data structure below. It is similar to the
one used for RT-throttling (rt_bandwidth), with the main difference
that, since here we are only interested in admission control, we
do not decrease any runtime while the group "executes", neither we
need a timer to replenish it.

With respect to SMP, bandwidth is given on a per root domain basis,
meaning that:
- bw (< 100%) is the deadline bandwidth of each CPU;
- total_bw is the currently allocated bandwidth in each root domain;

```
struct dl_bw {

     - * We try to cancel the timer first. If the callback is on
     - * flight on some other cpu then we let it handle it. If we
     - * were able to cancel the timer nothing can rearm it as we
     - * own broadcast_lock.
     + * This is called either from enter/exit idle code or from the
     + * broadcast handler. In all cases tick_broadcast_lock is held.
     */

 --- Open Source Used In 5GaaS Edge AC-4  32969 ---
However we can also be called from the event handler of
ce_broadcast_hrtimer itself when it expires. We cannot
restart the timer because we are in the callback, but we
can set the expiry time and let the callback return
HRTIMER_RESTART.

hrtimer_cancel() cannot be called here neither from the
broadcast handler nor from the enter/exit idle code. The idle
code can run into the problem described in bc_shutdown() and the
broadcast handler cannot wait for itself to complete for obvious
reasons.

Since we are in the idle loop at this point and because
hrtimer_{start/cancel} functions call into tracing,
calls to these functions must be bound within RCU_NONIDLE.
Each caller tries to arm the hrtimer on its own CPU, but if the
hrtimer callback function is currently running, then
hrtimer_start() cannot move it and the timer stays on the CPU on
which it is assigned at the moment.

As this can be called from idle code, the hrtimer_start()
invocation has to be wrapped with RCU_NONIDLE() as
hrtimer_start() can call into tracing.

RCU_NONIDLE({
		bc_moved = hrtimer_try_to_cancel(&bctimer) >= 0;
		if (bc_moved)
			hrtimer_start(&bctimer, expires,
		\HRTIMER_MODE_ABS_PINNED);});

    @@ -2540,10 +2549,10 @@
        * this way, and it
        * just so happens that it is the same bit corresponding to
        * the current context.
        *
        + * Now the TRANSITION bit breaks the above slightly. The TRANSITION bit
        + * is set when a recursion is detected at the current context, and if
        + * the TRANSITION bit is already set, it will fail the recursion.
        + * This is needed because there's a lag between the changing of
        + * interrupt context and updating the preempt count. In this case,
        + * a false positive will be found. To handle this, one extra recursion
        + * is allowed, and this is done by the TRANSITION bit. If the TRANSITION
        + * bit is already set, then it is considered a recursion and the function
ends. Otherwise, the TRANSITION bit is set, and that bit is returned.

On the trace_recursive_unlock(), the TRANSITION bit will be the first to be cleared. Even if it wasn't the context that set it. That is, if an interrupt comes in while NORMAL bit is set and the ring buffer is called before preempt_count() is updated, since the check will be on the NORMAL bit, the TRANSITION bit will then be set. If an NMI then comes in, it will set the NMI bit, but when the NMI code does the trace_recursive_unlock() it will clear the TRANSITION bit and leave the NMI bit set. But this is fine, because the interrupt code that set the TRANSITION bit will then clear the NMI bit when it calls trace_recursive_unlock(). If another NMI comes in, it will set the TRANSITION bit and continue.

Note: The TRANSITION bit only handles a single transition between context.

 * When function tracing occurs, the following steps are made:
 *   If arch does not support a ftrace feature:
 *    call internal function (uses INTERNAL bits) which calls...
-    * If callback is registered to the "global" list, the list
-    * function is called and recursion checks the GLOBAL bits.
-    * then this function calls...
-    * The function callback, which can use the FTRACE bits to
-        check for recursion.
-    *
-    * Now if the arch does not suppport a feature, and it calls
-    * the global list function which calls the ftrace callback
-    * all three of these steps will do a recursion protection.
-    * There's no reason to do one if the previous caller already
-    * did. The recursion that we are protecting against will
-    * go through the same steps again.
-    *
-    * To prevent the multiple recursion checks, if a recursion
-    * bit is set that is higher than the MAX bit of the current
-    * check, then we know that the check was made by the previous
-    * caller, and we can skip the current check.

Open Source Used In 5GaaS Edge AC-4  33181
This is the core CPRNG function. As "pseudorandom", this is not used
for truly valuable things, just intended to be a PITA to guess.
For maximum speed, we do just two SipHash rounds per word. This is
the same rate as 4 rounds per 64 bits that SipHash normally uses,
so hopefully it's reasonably secure.

There are two changes from the official SipHash finalization:
- We omit some constants XORed with v2 in the SipHash spec as irrelevant;
  they are there only to make the output rounds distinct from the input
  rounds, and this application has no input rounds.
- Rather than returning v0^v1^v2^v3, return v1+v3.
  If you look at the SipHash round, the last operation on v3 is
  "v3 ^= v0", so "v0 ^ v3" just undoes that, a waste of time.
  Likewise "v1 ^= v2". (The rotate of v2 makes a difference, but
  it still cancels out half of the bits in v2 for no benefit.)
  Second, since the last combining operation was xor, continue the
  pattern of alternating xor/add for a tiny bit of extra non-linearity.

/* Determine fan tunnel endpoint to send packet to, based on the inner IP address.
 * Given a /8 overlay and /16 underlay, for an overlay (inner) address Y.A.B.C, the transformation is F.G.A.B, where "F" and "G" are the first two octets of the underlay network (the network portion of a /16), "A" and "B" are the low order two octets of the underlay network host (the host portion of a /16), and "Y" is a configured first octet of the overlay network.
 * E.g., underlay host 10.88.3.4/16 with an overlay of 99.0.0.0/8 would host overlay subnet 99.3.4.0/24. An overlay network datagram from 99.3.4.5 to 99.6.7.8, would be directed to underlay host 10.88.6.7, which hosts overlay network subnet 99.6.7.0/24. This transformation is described in detail further below.
 * Using netmasks for the overlay and underlay other than /8 and /16, as shown above, can yield larger (or smaller) overlay subnets, with the trade-off of allowing fewer (or more) underlay hosts to participate.
 * The size of each overlay network subnet is defined by the total of the network mask of the overlay plus the size of host portion of the underlay network. In the above example, /8 + /16 = /24.
 * E.g., consider underlay host 10.99.238.5/20 and overlay 99.0.0.0/8. In this case, the network portion of the underlay is 10.99.224.0/20, and the host portion is 0.0.14.5 (12 bits). To determine the overlay...
+ network subnet, the 12 bits of host portion are left shifted 12 bits
+ (/20 - /8) and ORed with the overlay subnet prefix. This yields an
+ overlay subnet of 99.224.80/20, composed of 8 bits overlay, followed by
+ 12 bits underlay. This yields 12 bits in the overlay network portion,
+ allowing for 4094 addresses in each overlay network subnet. The
+ trade-off is that fewer hosts may participate in the underlay network,
+ as it's host address size has shrunk from 16 bits (65534 addresses) in
+ the first example to 12 bits (4094 addresses) here.

+ For fewer hosts per overlay subnet (permitting a larger number of
+ underlay hosts to participate), the underlay netmask may be made
+ smaller.

+ E.g., underlay host 10.111.12/12 (network 10.96.0.0/12, host portion
+ is 0.15.1.2, 20 bits) with an overlay of 33.0.0.0/8 would left shift
+ the 20 bits of host by 4 (so that it's highest order bit is adjacent to
+ the lowest order bit of the /8 overlay). This yields an overlay subnet
+ of 33.240.16.32/28 (8 bits overlay, 20 bits from the host portion of
+ the underlay). This provides more addresses for the underlay network
+ (approximately 2^20), but each host's segment of the overlay provides
+ only 4 bits of addresses (14 usable).

+ It is also possible to adjust the overlay subnet.

+ For an overlay of 240.0.0.0/5 and underlay of 10.88.0.0/20, consider
+ underlay host 10.88.129.2; the 12 bits of host, 0.0.1.2, are left
+ shifted 15 bits (/20 - /5), yielding an overlay network of
+ 240.129.0.0/17. An underlay host of 10.88.244.215 would yield an
+ overlay network of 242.107.128.0/17.

+ For an overlay of 100.64.0.0/10 and underlay of 10.224.220.0/24, for
+ underlay host 10.224.220.10, the underlay host portion (.10) is left
+ shifted 14 bits, yielding an overlay network subnet of 100.66.128.0/18.
+ This would permit 254 addresses on the underlay, with each overlay
+ segment providing approximately 2^14 - 2 addresses (16382).

+ For packets being encapsulated, the overlay network destination IP
+ address is deconstructed into its overlay and underlay-derived
+ portions. The underlay portion (determined by the overlay mask and
+ overlay subnet mask) is right shifted according to the size of the
+ underlay network mask. This value is then ORed with the network
+ portion of the underlay network to produce the underlay network
+ destination for the encapsulated datagram.

+ For example, using the initial example of underlay 10.88.3.4/16 and
+ overlay 99.0.0.0/8, with underlay host 10.88.3.4/16 providing overlay
+ subnet 99.3.4.0/24 with specific host 99.3.4.5. A datagram from
+ 99.3.4.5 to 99.6.7.8 would first have the underlay host derived portion
of the address extracted. This is a number of bits equal to underlay
network host portion. In the destination address, the highest order of
these bits is one bit lower than the lowest order bit from the overlay
network mask.

Using the sample value, 99.6.7.8, the overlay mask is /8, and the
underlay mask is /16 (leaving 16 bits for the host portion). The bits
to be shifted are the middle two octets, 0.6.7.0, as this is 99.6.7.8
ANDed with the mask 0x00ffff00 (which is 16 bits, the highest order of
which is 1 bit lower than the lowest order overlay address bit).

These octets, 0.6.7.0, are then right shifted 8 bits, yielding 0.0.6.7.
This value is then ORed with the underlay network portion,
10.88.0.0/16, providing 10.88.6.7 as the final underlay destination for
the encapsulated datagram.

Another transform using the final example: overlay 100.64.0.0/10 and
underlay 10.224.220.0/24. Consider overlay address 100.66.128.1
sending a datagram to 100.66.200.5. In this case, 8 bits (the host
portion size of 10.224.220.0/24) beginning after the 100.64/10 overlay
prefix are masked off, yielding 0.2.192.0. This is right shifted 14
(32 - 10 - (32 - 24), i.e., the number of bits between the overlay
network portion and the underlay host portion) bits, yielding 0.0.0.11.
This is ORed with the underlay network portion, 10.224.220.0/24, giving
the underlay destination of 10.224.220.11 for overlay destination
100.66.200.5.

    depends on NETFILTER_ADVANCED
    ---help---
    This option adds a 'CHECKSUM' target, which can be used in the iptables mangle
-    table.
+    table to work around buggy DHCP clients in virtualized environments.

-    You can use this target to compute and fill in the checksum in
-    a packet that lacks a checksum. This is particularly useful,
-    if you need to work around old applications such as dhcp clients,
-    that do not work well with checksum offloads, but don't want to disable
-    checksum offload in your device.
+    Some old DHCP clients drop packets because they are not aware
+    that the checksum would normally be offloaded to hardware and
+    thus should be considered valid.
+    This target can be used to fill in the checksum using iptables
+    when such packets are sent via a virtual network device.

    To compile it as a module, choose M here. If unsure, say N.
